K.N. is a 66-year-old man with stage IV non-small cell lung cancer. He was admitted with a fractured right hip that was caused by a fall. His appearance was older than his stated age, he was cachectic and debilitated, and his gait was unsteady. He smelled strongly of tobacco and reported smoking three to four packs of cigarettes each day for years. In addition, he stated that he used alcohol for many years and reported that he drank a fifth of whiskey every day, including the day of his fall. K.N. was pleasant and cooperative but did not seem to understand complex questions. He was provided an around-the-clock observer from the first day of his admission because the nurses deemed it unsafe for him to be alone.

The physician’s admitting orders included IV fluids. Knowing that K.N. had cancer, the RN assessed him for a port. When asked, K.N. indicated that he had a port. His frame was thin and his ribs were visible. Positioned over the right subclavicular area in the midclavicular line was what appeared to be a port. It was palpated and found to be firm and mobile with a fluctuant anterior face. It was prepped and found to be firm and mobile with a fluctuant area. The RN did not feel the firm back of the port. Blood return was negative. She removed the needle and called the IV team RN to access the port. After experiencing the same results, the IV team RN reported the port as nonfunctioning to the advanced practice nurse (APN) and noted that she could not find a record of the port insertion in the medical records of the facility.

The APN reviewed K.N.’s radiographic records and found no mention of a port in any of the films that included the chest. She then examined the films, but no port was visible on any of the x-rays or computed tomography (CT) scans. However, on the CT scans, a mass that was not described on the CT report was evident in the exact area of the presumed port. A radiologist was called, and the mass was characterized as being bunched pectoralis muscle, with a fluid-filled sebaceous cyst measuring 1.6 cm overlying the muscle (see Figure 1).

**Procedure-Related Risk Factors**

**Pneumothorax**

Pneumothorax is a risk with any puncture of the chest wall. When placing subclavian lines, the risk ranges from 1%–6% and may not develop for 48–72 hours after the procedure (Shapiro & Angood, 2005).

Determining whether K.N.’s risk was higher than the expected range for an approved procedure is difficult. The mass or lesion that was being punctured by the needle was somewhat lower on the chest wall than the usual subclavian approach. The usual landmark for subclavian catheter placement is just below the clavicle, placing the puncture above the first rib (Gomella & Haist, 2007). The mass or lesion was slightly lower on the chest wall between the first and second ribs, meaning that the puncture was in closer proximity to the dome of the right lung. The length of the needle was one inch; given the patient’s cachectic condition, the needle could have entered the pleural cavity.

**Hematoma**

The risk of hematoma is associated primarily with arterial puncture during central venous catheter insertion, which carries a risk as high as 15% with subclavian line insertion (Shapiro & Angood, 2005). The risk of hematoma with arterial nicking occurs because of the relative noncompressibility of any vascular structures behind the chest wall (McConville & Kress, 2005). A remote possibility of arterial puncture exists. In K.N.’s case, he had the added risk of possible hepatic-induced coagulopathy secondary to his long-term alcohol use (Handin, 2005).

**Infection**

The risk of infection with central venous access devices arises from the interruption of the skin barrier and the introduction of the catheter portal for bacterial invasion (McConville & Kress, 2005). In a study of 67 women with pelvic cancers, 70 catheters were placed successfully and only two ports
became infected (Nelson, Mayer, Tseng, & Schwartz, 1994). K.N. was not exposed to prolonged catheterization; therefore, the risk of systemic infection from the attempted cannulations was nonexistent. The skin barrier was broken by repeated punctures, and the cyst was a nonpurulent fluid- or keratin-filled cavity. The repeated punctures may have introduced bacteria into the cystic medium, resulting in local infection.

Other Risks

The remaining risks associated with the insertion of central venous access devices and the puncture of K.N.’s chest wall are cardiac tamponade, hemothorax, hydrothorax, air embolus, brachial nerve plexus injury, thoracic duct injury, and infection (Arch, 2007). The likelihood of those complications occurring was very small given the depth and location of the needle puncture.

Case Study Discussion

Nurses often rely on patients’ verbal history of a port; however, that assumption will fail when communication barriers, language barriers, or mental incapacity exist. In the case study, K.N. was mentally compromised, requiring an observer to keep him safe while in the hospital.

With the advent of CT power-injectable implanted ports, strict verification procedures are recommended prior to accessing a port and injecting dye with power injectors because of the potential risk of catheter rupture. Procedures include verifying the patient’s port identification card, identification wrist bands, and port placement records, and palpating for differences in shape of the port (Bard Access Devices, 2008; Camp-Sorrell, 2004). However, for noninjectable ports such as the port described in the case study, past standard practices for nursing instruction of port verification is limited to the type of port (i.e., open- or closed-ended), regarding whether the port needs to be flushed with saline or heparin solution. Access guidelines do not mention any other time for nurse verification of the port type from the patient records (Camp-Sorrell). Examination of the implanted port and patient history are sufficient for verification of the port (Arch, 2007; Camp-Sorrell). K.N. experienced no adverse outcomes from the needle sticks to the chest wall. The cyst did become superﬁcially infected but it responded well to topical antibiotic ointment. The situation was highly unusual in that the patient had a chest wall mass that had the location, consistency, and appearance of an implanted port. In addition, K.N. was unable to understand the question regarding the presence of the port, making this situation unlikely to be repeated. Changes have been made to the hospital’s policy and the nurses were commended for seeking proper validation when the port did not function as expected. The experience with this patient is an important reminder to assume nothing and to expect the unexpected.
