Background: Chemotherapy-induced peripheral neuropathy (CIPN) is a common and often dose-limiting side effect of chemotherapy that can result in disability and poorer quality of life. However, no standardized measurement for CIPN exists. Clinicians often base decisions for dose modification or discontinuation of a chemotherapeutic agent on patient report of subjective symptoms and physical examination.

Objectives: This review is designed to identify valid and reliable assessment tools that measure or assess CIPN in adult patients receiving chemotherapy.

Methods: A systematic literature review was conducted using PubMed, CINAHL®, and Cochrane Library. Articles were included if their primary purpose was to evaluate the psychometric properties of scales to measure CIPN in adult patients with cancer receiving neurotoxic chemotherapeutic agents.

Findings: The search yielded 143 results, with 16 articles meeting criteria for inclusion in the review. Seven unique scales and their reduced and modified versions were examined. The majority of the questionnaires were evaluated in a single tumor type, primarily with taxanes and platinum compounds. No consensus exists on the most appropriate patient self-report scale for use in the general oncology population.

Clinical Journal of Oncology Nursing  •  Volume 20, Number 2  •  Assessing Chemotherapy-Induced Peripheral Neuropathy...
Methods

A literature review was conducted in PubMed, CINAHL®, and the Cochrane Library using the following key words and medical subject headings (MeSH) terms: neoplasms with subheading drug therapy, antineoplastic agents, peripheral nervous system diseases with subheading chemically induced, questionnaires, neurotoxicity, neuropathy, severity of illness index, and instrument®. Search terms were combined using the words “AND” and “OR.” A manual search was also performed by reviewing the reference lists of included articles for additional publications.

Articles were included in the review if (a) the primary purpose was to evaluate the psychometric properties of the scale or questionnaire, (b) the sample included patients who had cancer and were either receiving or had received neurotoxic chemotherapeutic agents, and (c) the article included an assessment of CIPN by a patient report scale or questionnaire. Articles were limited to those that included adult patients aged 18 years or older and were published in English. No limits were placed on the date of publication.

Articles were excluded if they were a review, an editorial, or a commentary; if the study was performed in a setting that was other than oncology; the focus of the article was on prevention or treatment of CIPN; or only clinician toxicity scales were evaluated (i.e., the study did not evaluate a patient self-assessment of CIPN).

Results

The PubMed and CINAHL searches yielded 143 results. No articles from the Cochrane Library search were used. Sixteen of the 143 articles met the criteria for inclusion (see Table 1). The articles described seven scales or questionnaires to assess CIPN and their reduced or modified versions. The instruments included the Peripheral Neuropathy Scale (PNS); Functional Assessment of Cancer Therapy/Gynecologic Oncology Group (FACT/GOG)–Neurotoxicity (Ntx), –Taxane, and –Neurotoxicity 12 (Ntx12) subscales; the Total Neuropathy Score (TNS) and its other versions (reduced, clinical, modified, and reduced short form); the Patient Neurotoxicity Questionnaire (PNQ); the Scale for Chemotherapy-Induced Long-Term Neuropathy (SCIN); the Quality of Life Questionnaire-CIPN20 (QLQ-CIPN20); and the CIPN Assessment Tool (CIPNAT).

Peripheral Neuropathy Scale

One article reported psychometric testing of the PNS questionnaire (Almadrones, McGuire, Walczak, Florio, & Tian, 2004), a self-report, 11-item Likert-type scale developed based on common complaints expressed by patients receiving neurotoxic chemotherapy for ovarian cancer. Questions on the PNS pertain to physical function (e.g., eating, dressing, ability to walk short distances, bending) and role function (e.g., ability to work outside the home, ability to perform household chores). Content validity was established by an expert panel of patients and physicians familiar with the symptoms (Ostchega, Donohue, & Fox, 1988). The reliability of the PNS was acceptable, with Cronbach alphas of 0.91 and 0.89 at T1 (baseline) and T2 (after six cycles of chemotherapeutic agents and taxanes, well-known neurotoxic drugs (Almadrones et al., 2004). In addition, the questionnaire was clinically sensitive in that the scores changed significantly from T1 to T2 (p < 0.05) (Almadrones et al., 2004).

Functional Assessment of Cancer Therapy

Four articles reported psychometric testing of the FACT/GOG-Ntx, FACT/GOG-Taxane, and FACT/GOG-Ntx12 subscales. The FACT/GOG-Ntx contains 11 items scored from 0–4, and scores are summed for a range of 11–44. Questions on the Ntx subscale pertain to the feeling of weakness all over, numbness or tingling in the hands or feet, and difficulty buttoning their buttons. The FACT/GOG-Ntx was initially developed with the input of expert clinicians and patients who reported symptoms of CIPN within the past month (Calhoun et al., 2003). The questionnaire was validated with women diagnosed with gynecologic malignancies who received taxanes and platinum compounds, and skin discoloration. The FACT/GOG-Taxane has been used with patients non-small cell lung cancer who received platinum compounds and taxanes. The questionnaire had good reliability (Cronbach alpha = 0.84–0.88). The scale was also responsive to the changes in CIPN over time (p < 0.05).

Kopeck et al. (2006) modified the FACT/GOG-Ntx by adding one item specific to oxaliplatin (Eloxatin®) and renamed this version the FACT/GOG-Ntx12. The revised version was tested in patients with colon cancer. Reliability was good (Cronbach alpha = 0.85), and the questionnaire scores were correlated with the National Cancer Institute-Sanofi criteria. The FACT/GOG-Ntx was also shown to be sensitive to changes in CIPN over time.

Total Neuropathy Score

Five studies examined the psychometric properties of the TNS and its other versions. The TNS was initially designed to evaluate diabetic neuropathy (Cornblath et al., 1999) and was later validated in patients with cancer experiencing neuropathy (Cavaletti et al., 2003). The TNS includes objective measures, such as pin prick, vibration threshold, and nerve conduction...

Studies, combined with subjective report of sensory, motor, and autonomic items (Cavaletti et al., 2003). The instrument has been tested in a variety of tumor types that were treated with platinum-derived compounds, taxanes, thalidomide, or vinca alkaloids.

The TNS and its other versions were compared to several measures to assess validity, including the National Cancer Institute Common Toxicity Criteria (NCI CTC). Ajani grading scale, Eastern Cooperative Oncology Group (ECOG) grading scale, pin prick, vibration, balance, physical performance, and quality of life (Cavaletti et al., 2005, 2006, 2007). The TNS score highly correlated with NCI CTC, Ajani, and ECOG score (r = 0.654–0.75, 0.676, and 0.666, respectively) and was more sensitive than the NCI CTC in severe cases of CIPN (Cavaletti et al., 2003, 2007). Reduced versions of the TNS were developed because the original instrument was time consuming (about one hour to complete), and oncology practices cannot perform nerve conduction studies.

The TNSr excluded the motor symptoms, autonomic symptoms, and vibration sensation sections of the TNS. The TNSr correlated with the TNS (r = 0.98) (Cavaletti et al., 2005). Cavaletti et al. (2006) demonstrated that the TNSr was moderately to strongly correlated with the NCI CTC sensory, ECOG sensory, NCI CTC motor, and ECOG motor scales (r = 0.738, 0.709, 0.518, and 0.516, respectively). The NCI CTC sensory scale and the ECOG sensory scale are a provider-graded scale ranging from 0–5, where 0 indicates the absence of paresthesia and normal deep tendon reflexes and 3 indicates severe sensory loss or paresthesia that interferes with function. The NCI CTC motor scale and the ECOG motor scale are provider-graded scales ranging from 0–4, where 0 indicates motor weakness and 4 indicates paralysis.

The TNSc is a clinical version of the TNS scale and evaluates only clinical signs and symptoms of CIPN. Cavaletti et al. (2007) tested this scale in patients receiving platinum-derived compounds, taxanes, or thalidomide. TNSc scores correlated with the total NCI CTC (r = 0.88) (Cavaletti et al., 2007). In addition, the TNSc correlated in varying degrees with the NCI CTC sensory, ECOG sensory, NCI CTC motor, and ECOG motor scales (r = 0.666, 0.747, 0.491, and 0.492, respectively) (Cavaletti et al., 2006). Differences in TNSc score changes were highly significant, demonstrating that the TNSc is more sensitive in identifying sensory and motor components of CIPN than the NCI CTC (Cavaletti et al., 2007).

Wampler et al. (2006) tested the modified TNS (mTNS) in patients with breast cancer receiving taxane therapy. The mTNS is a modified version of the TNS, excluding the nerve conduction studies. The mTNS and TNS were highly correlated (r = 0.99, p < 0.001). In addition, the mTNS discriminated between the treatment and control groups.

Smith, Cohen, Pett, and Beck (2010) performed additional psychometric testing with the TNSr and a chemotherapy-induced neuropathy–specific pain scale (NPS-CIN). Reliability of the TNSr was poor (Cronbach alpha = 0.56), and the reliability of the NPS-CIN was excellent (Cronbach alpha = 0.96), leading to deletion or modification of several items. The new scale was renamed the TNSr-Short Form (TNSr-SF). Factor analysis demonstrated that the TNSr-SF and NPS-CIN formed two distinct factors, providing evidence of structural validity (Smith et al., 2010).

Patient Neurotoxicity Questionnaire

The psychometric properties of the PNQ were reported in two articles. This questionnaire consists of two items that identify the incidence and severity of sensory and motor disturbances, with reference to the sensory and neuromotor components of the clinician-based NCI CTC instrument (Shimozuma et al., 2009). The developers of the PNQ spent years interviewing and eliciting information on key symptoms of CIPN (Shimozuma et al., 2009). The sensory PNQ grade was moderately correlated with the sensory NCI CTC grade (r = 0.58, p < 0.05) and the FACT-Taxane (r = 0.51), and the motor...
Quality of Life Questionnaire–Chemotherapy-Induced Peripheral Neuropathy 20

The psychometric properties of the QLQ-CIPN20 questionnaire were reported in two articles. This 20-item questionnaire evaluates sensory, motor, and autonomic symptoms and is scored using a four-point Likert-type scale ranging from 1 (not at all) to 4 (very much). Sensory raw scale scores range from 1–36, motor raw scale scores range from 1–32, and autonomic raw scale scores range from 1–12 for men and 1–8 for women. All scale scores are linearly converted to a 0–100 scale, with higher scores indicating more symptoms. The generation of items for the QLQ-CIPN20 scale was described in detail by Postma et al. (2005). Content validity included review by a panel of 15 physicians. Internal consistencies were acceptable to good (Cronbach alpha = 0.82–0.88, 0.73–0.88, and 0.76–0.78 for the sensory, motor, and autonomic scales, respectively) (Lavoie Smith et al., 2013a; Postma et al., 2005). However, low item-item correlations were found between the items on the autonomic scale and hearing loss (r ≤ 0.3) (Lavoie Smith et al., 2013a). Construct validity was measured using confirmatory factor analysis, which revealed a statistically significant chi-square (X² = 2,462.09, p < 0.01), indicating a poor fit. Exploratory factor analysis performed using Bartlett's test of sphericity indicated that the correlation matrix was favorable (X² = 653.81, p = 0.0001), and the Kaiser-Meyer-Olkin (KMO) measure of sampling adequacy was adequate at 0.83. Convergent validity was evaluated by comparing the QLQ-CIPN20 with other neuropathy measures; correlations with the Common Terminology Criteria for Adverse Events (CTCAE) sensory grading scale were weak (r = −0.2, 0.2, and 0.03, respectively), and the correlations with Brief Pain Inventory–Short Form (BPI-SF) pain severity questions were weak to moderate. Responsiveness to change over time was evaluated by calculating effect size (Cohen’s d). Based on change in sensory scores, effects were 0.82 and 0.48 for the motor scale.

Scale for Chemotherapy-Induced Long-Term Neuropathy

Oldenburg, Fossa, and Dahl (2006) reported the psychometric properties of the SCIN, which has three subscales: neuropathy (two items), Raynaud’s phenomenon (two items), and otoxicity (two items). The SCIN questionnaire was initially developed based on interviews with testicular cancer survivors (TCSs) and a review of the literature on long-term morbidity in TCSs. The SCIN was tested with 206 TCSs, but limited psychometric evaluation was performed (Oldenburg et al., 2006). Internal consistency was reported at greater than 0.7. Oldenburg et al. (2006) used the known group’s technique to measure construct validity. A significant difference was found in scores between the chemotherapy alone group and the radiation or surgery alone group (p < 0.001), indicating that the questionnaire accurately discriminates between these groups. Criterion validity was measured by comparing the scale scores with subjective measures of CIPN, such as clinician-based toxicity criteria and other self-report neuropathy scales.

Chemotherapy-Induced Peripheral Neuropathy Assessment Tool

The psychometric properties of the CIPNAT questionnaire were described in one article. The CIPNAT was developed based on the Theory of Unpleasant Symptoms (Lenz, Pugh, Milligan, Gift, & Suppe, 1997), with information obtained from 14 people with CIPN, and was validated by five experts who recommended minor revisions (Toftthagen, McMillan, & Kip, 2011). The questionnaire contains 36 items that evaluate the occurrence, severity, distress, and frequency of nine neuropathic symptoms and 14 items that evaluate neuropathic interference with activities. Mean scores on the CIPNAT of patients expected to have symptoms of neurotoxicity and scores of a comparison group differed significantly (t = 7.66, p < 0.01), and scores on the CIPNAT and the FACT/GOG-Ntx were highly correlated (r = 0.83, p < 0.001, n = 167). Test-retest reliability was excellent for the total CIPNAT, symptom experience, and interference items (r = 0.93, 0.89, 0.93, respectively; p < 0.001). Cronbach alphas were excellent for the total CIPNAT, the symptom experience items, and the interference items (Cronbach alpha = 0.95, 0.93, and 0.91, respectively).

Discussion

No clear consensus exists on what is the most appropriate patient self-report instrument for assessing CIPN. The FACT/GOG-Ntx and TNS (and its other versions) have been extensively studied. The FACT/GOG-Ntx has acceptable reliability and validity and is recommended for use in patients with gynecologic malignancies. However, additional studies should be conducted with other tumor types to determine if this scale is valid and reliable in these populations. The original TNS is not feasible for use in routine practice because it includes nerve conduction studies. The simplified versions of the TNS scale, including the TNSc, Tnsr, TNSr-SF, and mTNS, appear to be valid; however, data on the reliability of the mTNS and TNSr-SF are lacking, and continued psychometric testing is recommended.

The PNS, FACT-Taxane, PNQ, QIQ-CIPN20, and CIPNAT have been studied in limited ways. The FACT-Taxane and PNQ appear to be valid questionnaires to measure sensory symptoms associated with CIPN, but reliability data are lacking. Additional psychometric testing is recommended before routine use of these tools can be recommended. The PNS, QIQ-CIPN20, and CIPNAT all appear to be valid and reliable, but, because a limited number of studies have evaluated these tools, routine use is not recommended at this time.

The SCIN has been validated in patients who had previously received chemotherapy, but it is unclear whether the SCIN is appropriate for use in patients actively receiving chemotherapy. Therefore, data to recommend the use of the SCIN are lacking.

One issue with psychometric testing of CIPN instruments is that it is not entirely clear what is the most appropriate method.
Implications for Practice

- Assess for chemotherapy-induced peripheral neuropathy (CIPN) using a combination of subjective and objective measures.
- Use the Functional Assessment of Cancer Therapy/Gynecologic Oncology Group—Neurotoxicity to assess CIPN in patients with gynecologic malignancies undergoing chemotherapy.
- Consider the Total Neuropathy Score—clinical for use in a broader oncology population because this scale has been tested on more than one tumor type.

to test criterion validity of these scales. Objective measures, such as nerve conduction studies to detect increases in neuropathy, have produced inconsistent findings, and the findings also tend to correlate poorly with subjective reports by patients, who have a tendency to underreport (Stubblefield et al., 2009). Comparisons to clinician-rated toxicity scales show poor correlations between objective findings and patient-reported severity of symptoms (Stubblefield et al., 2009).

Other limitations to the studies also existed. Many included patients with only one tumor type, limiting the ability to use these instruments with other tumors. Tumor types commonly treated with neurotoxic chemotherapy drugs that were underrepresented included prostate cancer, non-Hodgkin lymphoma, and multiple myeloma. In addition, platinum agents and taxanes were the most commonly used neurotoxic agents in these studies, making it difficult to translate the results to other neurotoxic chemotherapeutic agents commonly used in cancer treatment. Additional testing of the instruments needs to be performed with other tumor types to validate these scales for the general oncology population. Testing also needs to be done with other neurotoxic drugs to determine the validity and reliability of the tools with other populations.

Several studies collected data on patients who had received neurotoxic chemotherapy previously (Cavaletti et al., 2007; Oldenburg et al., 2006; Postma et al., 2005; Shimozuma et al., 2009; Smith et al., 2010; Wampler et al., 2006). Confounding variables may have affected the CIPN scores and skewed the data. These questionnaires may not be valid or reliable to evaluate CIPN in patients undergoing active chemotherapy and help to make decisions about dose modification or discontinuation of neurotoxic drugs.

Implications for Practice and Conclusion

As more neurotoxic chemotherapeutic agents are used in clinical practice for many tumor types, clinicians need to become more vigilant in assessing CIPN to prevent irreversible neuropathy. Based on current research, the existing instruments should be used in conjunction with a thorough neurologic physical examination. The scales should be used only with the patient population for which there is evidence to do so until further testing for validity and reliability is done with other tumor types. The FACT/GOG-Ntx can be used to assess CIPN in patients with gynecologic malignancies undergoing chemotherapy. The TNSc could be considered for use with a broader oncology population because this scale has been tested on more than one tumor type.
